Will ageing lead to a higher real exchange rate for the Netherlands?

Maikel Volkerink, SEO Economic Research, Amsterdam

Abstract

Long-term projections for the Netherlands indicate that demand for nontradables – *e.g.* health care services – will increase relative to supply due to population ageing. If this leads to higher future real exchange rates this will erode the return of the savings currently made to prepare for ageing. This paper explores the magnitude of potential price effects using a modified version of the ‘two country, four commodity framework’ developed by Obstfeld and Rogoff (2005) to explore the exchange rate effects of the balance of payments reversal in the US. When these price effects are substantial, this may have serious consequences for policies to enhance national saving in the Netherlands.

Nederlandstalige samenvatting

Als gevolg van de vergrijzing zal op lange termijn de vraag naar binnenlandse diensten, met name in de zorg, toenemen in verhouding tot het aanbod. Omdat deze diensten niet internationaal verhandelbaar zijn, kunnen binnenlandse prijzen, en daarmee de reële wisselkoers, oplopen, waardoor het rendement op de besparingen wordt uitgehold. Dit paper verkent de mogelijke omvang van dergelijke prijseffecten op basis van een aangepaste versie van het twee-landen, vier-goederenmodel dat Obstfeld en Rogoff hebben ontwikkeld om de wisselkoerseffecten te onderzoeken van het tekort op de lopende rekening van de VS. Wanneer deze prijseffecten substantieel zijn, kan dat belangrijke gevolgen hebben voor het beleid dat erop is gericht om de toekomstige vergrijzing op te vangen door extra besparingen.

Key words: ageing, trade balance, nontradables, real exchange rate

1. Introduction¹

The Netherlands has run a surplus in the balance of payments since the beginning of the 1980s. Accumulated savings are welcome in view of the upcoming burden of population ageing in next decades. There are concerns, however, that the return on these savings may be eroded by higher prices when ageing comes true. There are two reasons why ageing – for a small open economy – may lead to higher (real) prices for domestic goods. First, population ageing will shift average preferences from tradables to nontradables as older people demand more domestic services than goods, in particular services related to health care and long term care. The increasing demand for nontradables may drive up prices if supply is restrained. Second, and more typical for the case of the Netherlands, future consumption will increase relative to domestic output when accumulated foreign savings are repatriated to keep up consumption for the ageing population. Long term projections for the Netherlands indicate that the trade balance will turn from a surplus of 7 percent of GDP in 2010 into a deficit of 3 percent when ageing reaches its peak in 2040. This reversal in the trade balance may affect domestic prices as demand for domestic goods increases relative to output.

In this paper, we explore the scope and magnitude of (real) price effects on the intertemporal price of consumption in a simple stylized model for the Netherlands. In the projections underlying Dutch fiscal policies (Van der Horst et al., 2010, Bettendorf et al. 2011) any such price effects are neglected. Adopting a small open economy perspective, these projections assume prices to be given by world market prices. Although there are good reasons to assume that the economy is sufficiently flexible to eliminate any price effects in the long run, it is useful to explore the potential impact for more conservative views on the flexibility of the economy. If price effects do occur the projections on fiscal policies overstate the effectiveness of policies aiming at increasing national saving for ageing, as the rate of return on these savings may be eroded by higher future consumer prices. These price effects matter for fiscal policy, not only because they impact the government budget directly through the costs of government expenditures, but also because they alter the costs and benefits of austerity policies to restore sustainability. In effect, current older generations will benefit less from such policies, and the future young will benefit more as they reap the gains from the improvement in the terms of trade and from the higher wages. Accordingly, budgetary policies become less effective for the purpose of consumption smoothing over generations. Similarly, as the real rate of return declines, optimal consumption smoothing entails a lower tilt of the consumption path. That is, consumption becomes more expensive relative to consumption earlier in life.

In many respects, this future reversal in the Dutch trade balance mirrors the problem of reversal in US current account that has been analysed by Obstfeld and Rogoff (2005). The reversal is in opposite direction, however; while rebalancing of the US balance of payments requires the elimination of the current account deficit, rebalancing in the case of the Netherlands implies the transition from a surplus to a deficit. Accordingly, whereas the US faces a real depreciation, the

¹ Comments by Nick Draper and computational assistance by Arie ten Cate are gratefully acknowledged.

Netherlands will – in the future – experience a rise in the real exchange rate. Obstfeld and Rogoff (O&R) conclude that the dollar needs to depreciate by 20-25 percent to eliminate the current account deficit of about 6 percent of GDP in 2005. For the Netherlands the challenge is almost twice as large as the trade balance will change by 10 percent in total. If also the price effect would increase in proportion, this would imply a yearly real price increase of around 1 percent relative to the rest of the world during the entire period 2010-2040. This enormous price effect would however overstate the problem, as over a longer time horizon also supply can be expected to adjust, so that price effects are softened.

In this paper we will adopt the O&R framework to analyse the Dutch case, but with some important modifications. O&R assume a symmetric two region world (Home- Foreign) with four heterogeneous types of goods – Home and Foreign produced tradables, and nontradables in both countries –, and with fixed labour endowments for each of the sectors. This framework will be modified for the case of a small open economy, so that the price of foreign tradables can be taken as given. Furthermore, since our focus is on the long term we drop the assumption of fixed sectoral endowments, and allow for factor mobility between the two domestic sectors. Finally, we will allow preferences to change over time, thus taking account of the increasing share of nontradables in aggregate consumer spending. In other respects, we will follow O&R. Although the model is static in nature, we can use it for comparative statics by accounting for the evolution of the relevant variables using long term projections for the Dutch economy constructed by Van de Horst et al. (2010). This allows us to derive both the terms of trade effects, and price effects of domestic nontradables at different points in time in the future; we focus on 2040 when ageing reaches its peak, and the intermediate year, 2025.

Naturally, the impact of demand on relative prices over such a long time horizon is uncertain, and hinges on the mobility of production factors. It is often assumed that over such a long time horizon factor mobility will eradicate all price differentials. Yet, terms of trade effects seem to be quite persistent, even over longer time horizons (Cardi and Restout, 2011)). And there is ample evidence on imperfect mobility on labour markets. Lee and Wolpin (2006) find that switching across sectors does involve substantial costs to the individual ranged between 50 and 75 percent of annual earnings. Also flexibility upon entry in the labour market is less than perfect due to individual heterogeneity (Heckman and Sedlacek, 1985). Moreover, students seem to take little notice of wage differentials when choosing their type of study (Oosterbeek and Webbink, 1995). At the same time we see that wage ratios vary little in response to sectoral shifts. For example, while in the US the services sector employment in the period 1968-2000 grew 2.2 percent per year faster than in the goods industries, wages grew only by 0.2 percent faster. Possibly, organization of production in tasks and its spatial distribution may be more flexible than traditional sectoral models predict (Baldwin and Robert-Nicoud, 2010). In summary, there is a lot uncertainty on these issues, and the alternative positions on long-term price effects seem to be a matter of belief rather than of solid knowledge. Although we are inclined to believe that price effects are minor over a long time horizon, we think it

is useful to contribute to this debate by exploring the potential magnitude of such effects for more conservative views, and to gain insight into the sensitivity of the results to underlying assumptions.

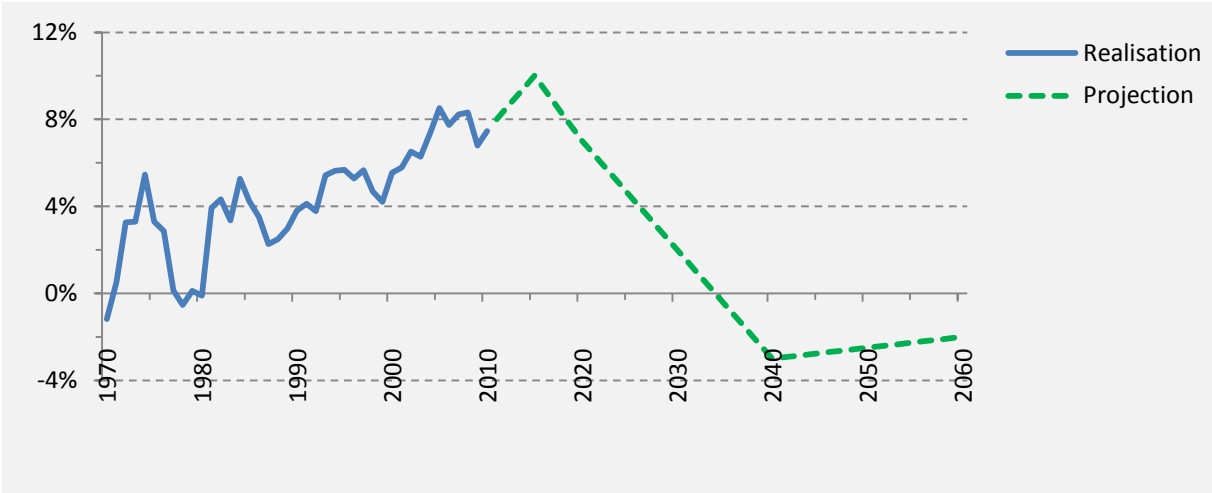

Our analysis is related to the literature on the growth of the services sector relative to the goods industries (*e.g.*, Iscan 2010), but only partially. In the present paper, we take underlying trends as given, and focus on the partial effects of ageing on relative prices across sectors. That is what matters for policies aimed at enhancing national savings to prepare for ageing.

The paper is organized as follows. Section 2 introduces the long term scenarios for the Netherlands, and derives aggregate consumer preferences for tradables and nontradables on the basis of household data. Section 3 presents the model, and section 4 presents the calibration and the numerical results for the medium term (the year 2025) and the long term (the year 2040).

2. Some stylized facts

From 1970 to 2010, the Netherlands has consistently built up a trade surplus from 0 percent in 1970 percent to 7 percent in 2010 (Figure 1). As a result the Netherlands has accumulated a net foreign asset position of about 30 percent of GDP by 2010 (DNB, 2011). The trade surplus is projected to remain high up to 2020; thereafter it steadily declines and turns into a deficit by 2040 when the demographic transition towards a greyer society is completed. This time path is consistent with a sustainable path of government finances which starts with a surplus in anticipation of the growing burden of pensions and other age related expenditures in the future. The deterioration in the trade balance is the net result of two effects of ageing: first, on the supply side output growth is restrained by the decline in working population, and second, on the demand side accumulated savings keep up purchasing power to smooth consumption when people become older on average. The reversal of the trade balance after 2030 is thus the natural complement of the ageing process.

Figure 1 Trade Balance (% GDP), historical and projected

Source: CBS (2011) for historical data; Van der Horst *et al.* (2010) for projections

When aggregate demand increases relative to domestic production, domestic prices may rise as a result leading to a higher real exchange rate. How much domestic prices rise depends on whether foreign substitutes are available for domestic goods. In case of perfect substitutability domestic prices will hardly react, but they may rise sharply if no substitutes are available. It is useful here to make a distinction between tradables and nontradables; tradables are sold both home and abroad whereas nontradables are supplied to the home market only. Restrictions on tradability follow from characteristics of the good (like a haircut or nursing), or institutional constraints like tariffs. It is generally assumed that higher domestic demand will in particular affect prices of nontradables – being excluded from trade across the border –, but that it may lead to higher prices of domestically produced ‘home’ tradables as well.

Age dependent consumption patterns

There is a second reason why demand for domestic nontradables will increase. Since older people spend more on domestic services than young people, ageing will also affect the aggregate preferences with regard to nontradables and tradables. This may be an additional factor driving up domestic prices. In the extreme, it is feared that growing demand for nontradable services on long term care and healthcare will make old age of current generations unaffordable. This is clearly overstated, but it is true rising costs of age related expenditures may put additional pressure on the ageing problem.

Empirical research on expenditure patterns of age-groups is still scarce. Börsch-Supan (2001) takes a brief look at the relation between age and consumer spending. By comparing budget shares for different consumption categories per age-group over time, he finds that consumption profiles differ across age indeed. Hobijn and Lagakos (2003) come to similar conclusions.² For instance, they find that budget shares for medical care by the elderly are twice as large as those of people of working age. Purchases on transportation, on the other hand, fall by a third. A problem in this type of research is that it cannot strictly separate time, cohort and age effects. Nevertheless Börsch-Supan suspects that age is the main determinant of the changes in spending behaviour; repeated cross-sectional analysis showed that the age-consumption profiles did not change much across age-groups during the 1980s and 1990s. Lührmann (2005 and 2008) has looked more carefully at this issue by controlling for age and time effects. She finds that both age and time effects matter, but age-effects are most substantial.

Age-profiles of tradables-nontradables consumption in the Netherlands

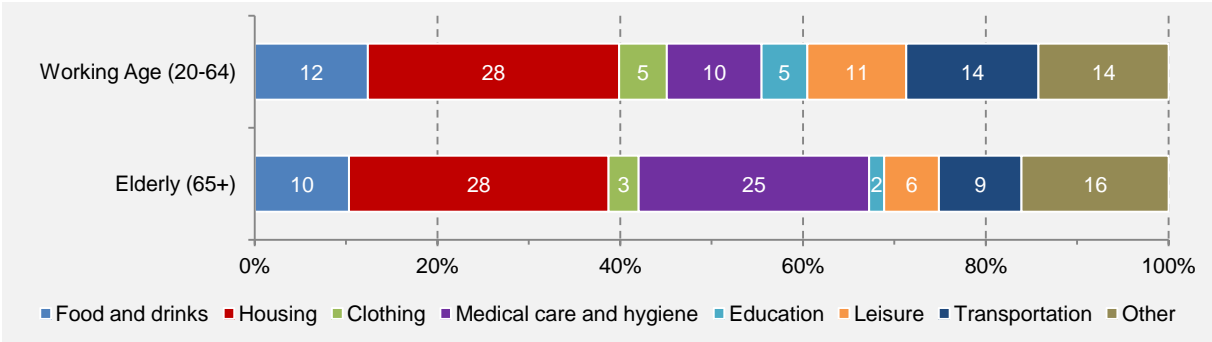

In this paper, we follow Börsch-Supan (2001) and derive age-consumption profiles using cross-sectional micro-data on household spending. Figure 2 presents budget shares per age group for the Netherlands for total expenditures, that is private and public expenditures combined.³ As expected,

² However, their research question is different. Hobijn and Lagakos criticise the consumer price index (CPI) that is used to index retirees' benefits.

³ Details on this decomposition are given in the Appendix.

the elderly spend a considerable larger part of their budget on healthcare and related goods and services. This increase in healthcare expenditures is compensated by smaller budget shares for transportation, leisure and education and clothing.

Figure 2 Budget shares total household spending (public and private) per age group

Source: own calculations based CBS (2010), Eurostat (2011) and Van der Horst *et al.* (2010)

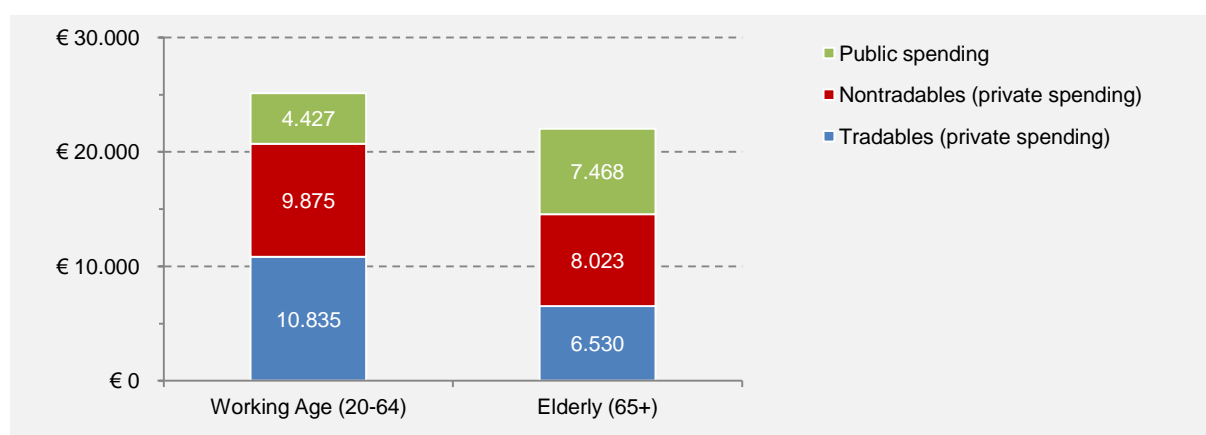

Detailed private consumption data, provided by Statistics Netherlands (CBS, 2010), makes it possible to distinguish between (manufactured) goods and services. Each of the 450 categories is classified as either tradable or nontradables; with a few exceptions, goods are classified as tradables and services are classified as nontradables.⁴

Public expenditure (on account of the consumer) is introduced as a separate category. Though we suspect most government services to be nontradable, the extend cannot be determined from the data. Data on government expenditures per age follows from Van der Horst *et al.* (2010). Expenditures on education are high for the young, health expenditures are substantial for the elderly. Expenditures on infrastructure, government services (like public administration and parliament) are distributed equally over the population.

Results of this reclassification for the consumption profile per age category are presented in Figure 3. The figure shows that elderly spend more on nontradables relative to tradables. In particular the large share of public spending for the elderly stands out.

⁴ See the Appendix for details.

Figure 3 Average expenditures per person, three categories, per age group

Source: own calculations based CBS (2010), Eurostat (2011) and Van der Horst *et al.* (2010)

Given these budget shares per age category and the Dutch demographic projections it is possible to calculate aggregate spending on each of these categories per year (see Table 1). The share of private consumption of tradables decreases from 40.5 percent in 2010 to 39.5 percent in 2025, and 38.7 percent in 2040. This mainly reflects the increase in public expenditures. If one only considers private consumption the shift is limited: in 2010 tradables make up 51.1 percent of private consumption, in 2040 this has fallen to 50.2 percent. If we do reckon public spending to nontradables the shift is more substantial, viz. from 59.5 percent for total nontradables consumption in 2010 to 61.3 percent in 2040, an increase of 1.8 percentage points.

Table 1 Projected budget shares for tradables and nontradables, 2010-2040

	2010	2025	2040
Share tradables (private consumption)	40,5 %	39,5 %	38,7 %
Share nontradables (private consumption)	38,7 %	38,5 %	38,3 %
Share public spending	20,8 %	22,0 %	23,0 %

Source: own calculations based CBS (2009, 2010), Eurostat (2011) and Van der Horst *et al.* (2010)

Alternative scenario: high growth of care expenditures

Table 1 expresses the demographic effects on spending shares only. That is, it takes account of the age effects, and neglects possible time effects on consumer preferences. Furthermore, differential effects of technological change are not accounted for either. Some people expect that expenditures on health care and long term care will grow faster due to rapid improvement in medical technology, and possibly due to Baumol and Wagner effects⁵ as well. Therefore we will consider an alternative scenario with high growth of public expenditures next to our baseline scenario. Van der Horst *et al.* (2010) distinguish an alternative scenario with 1 percent extra growth in public expenditures on

⁵ The Baumol effect refers to lower productivity change, and the Wagner effect to an income elasticity larger than one. Both factors may lead to a larger share of health care and long term care in total spending.

healthcare and long term care for the period 2010-2040. This will lead to a dramatic increase in total public expenditures by 2040 as can be seen from Figure 4.

Figure 4 Average expenditures per person, per age group in 2040 : high growth of care scenario

Source: own calculations based CBS (2010), Eurostat (2011) and Van der Horst *et al.* (2010)

Though these assumption are rather extreme, they provide an informative benchmark. Again we can calculate the evolution of aggregate spending shares for the high care expenditures scenario, see Table 2. In this case the share of tradables in total spending decreases by no less than 4.9 percentage points.

Table 2 Projected budget shares tradables and nontradables: high growth of care scenario

	2010	2025	2040
Share tradables (private consumption)	40,5 %	38,1 %	35,6 %
Share nontradables (private consumption)	38,7 %	37,1 %	34,8 %
Share public spending	20,8 %	24,8 %	29,6 %

3. The model

How demographic transition affects prices of nontradables and tradables can be explored using a modified version of the two-country model of Obstfeld and Rogoff (2005). Like Obstfeld and Rogoff (O&R) we use the model to analyse the impact of a change in demand on prices and the real exchange rate. The context is different though. While O&R use the model to assess the impact of an unwinding of the US current account deficit in the short run, we will focus on the reversal in the trade balance as ageing proceeds in the long run. In addition, ageing may also lead to a shift in consumption of tradables to nontradables as demand for old age care increases. The long term character of our problem requires the O&R model to be modified in one important respect: whereas O&R assume

production in each sector to be completely fixed, we will allow for flexibility in production in the medium and long term. In particular we drop the assumption of a fixed allocation of labour, and introduce long term mobility of labour across sectors. The total endowment of labour remains fixed. Furthermore, we focus on a small country relative to the rest of the world; this country is a price taker on foreign capital markets and markets for foreign tradables. Capital is perfectly mobile internationally. In other respects the model is similar, featuring two-countries (home versus the rest of the world), two-sectors (tradables and nontradables) and home bias as consumers prefer domestically produced tradables over tradables produced abroad. The model can be summarized as follows.

Prices

The demand side of the model specifies nested preferences of consumers with regard to the nontradables C_N and tradables C_T , with tradables being a composite of domestically produced tradables C_H and foreign tradables C_F .⁶ Using standard CES preferences one obtains the following prices for total domestic consumption (P) and the price of tradables P_T .

$$P = \left[\gamma P_T^{1-\theta} + (1-\gamma) P_N^{1-\theta} \right]^{\frac{1}{1-\theta}} \quad (1)$$

$$P_T = \left[\alpha P_H^{1-\eta} + (1-\alpha) P_F^{1-\eta} \right]^{\frac{1}{1-\eta}} \quad (2)$$

The price of consumption P depends on the prices for tradables P_T and nontradables P_N , and similarly the price of tradables P_T depends on prices of Home goods and Foreign goods, P_H and P_F . The preference parameters γ and α represent the shares spent on tradables and Home goods. Also, θ and

⁶ Consumer preferences with regard to nontradables and tradables are given by the CES function (for the home

country) $C = \left[\gamma^{\frac{1}{\theta}} C_T^{\frac{\theta-1}{\theta}} + (1-\gamma)^{\frac{1}{\theta}} C_N^{\frac{\theta-1}{\theta}} \right]^{\frac{\theta}{\theta-1}}$ where γ represents the share spent on tradables, and θ the elasticity

of substitution. In this function tradables C_T is a composite commodity depending on Home and Foreign produced

goods, C_H and C_F , given by $C_T = \left[\alpha^{\frac{1}{\eta}} C_H^{\frac{\eta-1}{\eta}} + (1-\alpha)^{\frac{1}{\eta}} C_F^{\frac{\eta-1}{\eta}} \right]^{\frac{\eta}{\eta-1}}$ and for the foreign country

$C_T^* = \left[\alpha^{*\frac{1}{\eta}} C_F^{*\frac{\eta^*-1}{\eta^*}} + (1-\alpha^*)^{\frac{1}{\eta^*}} C_H^{*\frac{\eta^*-1}{\eta^*}} \right]^{\frac{\eta^*}{\eta^*-1}}$ with elasticity η and preference for domestic tradables α . As

the two countries are of unequal size foreign country (indicated by asterisks) may have different α and γ coefficients: $\alpha < \alpha^*$, $\gamma > \gamma^*$.

η give the elasticities of substitution between consumption of tradables C_T and nontradables C_N , and Home and Foreign produced goods, C_H and C_F , respectively. With respect to tradables it is assumed that the law of one price holds, so that $P_F = P_F^*$ and $P_H = P_H^*$ where the asterisk denotes foreign variables. All prices are expressed in the same currency so that we can neglect nominal exchange rates. Note that the law of one price does not hold for baskets of tradables – as shares may differ –, and a fortiori for prices of nontradables and the general price level P , so , so $P_T \neq P_T^*$, and $P \neq P^*$. The small open economy assumption implies that changes in prices in the home country have a negligible impact on foreign prices as well as foreign consumption. The price of foreign tradables (P_F) is therefore taken as numeraire. Next define the following relative prices:

$$\tau = P_F / P_H \quad (\text{terms of trade})$$

$$x = P_N / P_T \quad (\text{relative price of nontradables})$$

More than in these static prices, we are in this paper interested in the intertemporal terms of trade that is the real interest rate r on national savings. This depends on the given world interest rate r^* (expressed in units of foreign tradables) and the real rate of appreciation:

$$1 + r = (1 + r^*) / P \quad (\text{real interest rate})$$

where the initial exchange rate – measured today – is normalized at unity. Higher future prices P thus imply a lower interest rate and thus worsen the intertemporal terms of trade. Obviously as ageing happens in the rest of the world as well, the world interest rate reflects the impact ageing as well. What matters for our analysis however is how domestic policies towards ageing affect the effective interest rate on national savings. In other words, do policies to promote national savings in the advent of ageing deteriorate the terms of trade, or in popular terms: will not future price rises due to scarcity of domestic goods erode the value of our savings for old age?

Demand and supply

Prices can be solved from demand and supply for the two domestically produced goods C_N and C_H . Optimising consumer behaviour – given the budget constraint $PC = P_T C_T + P_N C_N$ – leads to the following demand equations:

$$\frac{C_N}{C_T} = \frac{1-\gamma}{\gamma} \left(\frac{P_N}{P_T} \right)^{-\theta} \quad (3)$$

$$\frac{C_F}{C_H} = \frac{1-\alpha}{\alpha} \left(\frac{P_F}{P_H} \right)^{-\eta} \quad (4)$$

Next consider the supply side. As we focus on the long run we have to modify the O&R model in one important respect. Rather than assuming a fixed endowment economy we allow for flexibility in production factors across sectors. More specific, we assume labour to be mobile. This flexibility is not perfect, as workers have preferences for working in either sector. This could be interpreted that workers are heterogeneous and that each sector requires specific skills which cannot be acquired costlessly. Even though ageing is a process that will take several decades to reach its peak, the working population can only slowly adjust to new requirements with regard to skills. We capture this by the following relation for the allocation of labour to the tradable sector L_H and nontradables sector L_T :

$$\frac{L_N}{L_H} = \lambda \left(\frac{w_N}{w_H} \right)^\psi \quad (5)$$

where ψ represents the substitution elasticity of labour across sectors, and λ the preference for working in the nontradables sector.⁷ Total labour supply is fixed by population size L , giving the resource constraint

$$L = \frac{Y_N}{A_N} + \frac{Y_H}{A_H} \quad (6)$$

where Y_i and A_i stand for production and average labour productivity in sector i with $i \in \{N, H\}$, thus $Y_i = A_i L_i$. If capital can freely move between the two sectors, and production features constant returns to scale, wages in either sector are given by prices and average productivities, therefore

$$\frac{w_N}{w_H} = \frac{A_N P_N}{A_H P_H}$$

Adopting a simple Cobb Douglas production function $Y_i = K_i^{\frac{\beta}{1+\beta}} (M_i L_i)^{\frac{1}{1+\beta}}$ this labour productivity is given by

⁷ This follows from preferences with regard to work in either sector $U = \left[\frac{\lambda}{1+\lambda} \frac{1}{\psi} L_N^{\frac{\psi-1}{\psi}} + \frac{1}{1+\lambda} \frac{1}{\psi} L_H^{\frac{\psi-1}{\psi}} \right]^{\frac{\psi}{\psi-1}}$

$$A_i = \left(\frac{\beta}{1+\beta} \frac{1}{r} \frac{P_i}{P_F} \right)^\beta M_i \quad (7)$$

where $r P_F$ stands for the rental price of capital goods, which are owned abroad. Collecting these results we can solve for production in the two sectors:

$$\frac{Y_N}{Y_H} = \lambda \left(\frac{M_N}{M_H} \right)^{1+\psi} \left(\frac{P_N}{P_H} \right)^{\psi+\beta(1+\psi)} \quad (8)$$

The production allocation varies with prices depending on labour elasticity ψ and the capital elasticity (β). Without loss of generality we can assume $M_N/M_H = 1$ so that λ captures both preferences and productivity.

Aggregate equilibrium

Aggregate consumption depends on the intertemporal equilibrium of saving and wealth. As we focus on the prices effects of the reversal in the balance of trade, we take total wealth – and thus the amount people can spend on consumption – as given in terms of foreign prices. The volume of consumption, as well as its composition, are endogenously determined in aggregate equilibrium. In addition to this effect of ageing through the balance of trade effect, we also take account of the impact of ageing on aggregate consumer preferences, represented here by a shift in the share of tradables γ . The trade balance is given by

$$B = P_H Y_H - P_T C_T$$

Using the demand equations (3) and (4) and the condition that in equilibrium production of home tradables must equal the sum of domestic and foreign demand, $Y_H = C_H + C_H^*$ this can be written as

$$B = \frac{(1-\alpha^*)}{\alpha^* \tau^{1-\eta^*} + (1-\alpha^*)} P_T^* C_T^* - \frac{(1-\alpha)\tau^{1-\eta}}{\alpha + (1-\alpha)\tau^{1-\eta}} P_T C_T$$

where the first term on the right hand side represents foreign demand for Home tradables (in value terms) and the second term net domestic demand for tradables. Normalizing this result to the given foreign consumption of tradables $P_T^* C_T^*$ gives:

$$b = \frac{(1-\alpha^*)}{\alpha^* \tau^{1-\eta^*} + (1-\alpha^*)} - \frac{(1-\alpha)\tau^{1-\eta}}{\alpha + (1-\alpha)\tau^{1-\eta}} h \quad (9)$$

where $h (= P_T C_T / P_T^* C_T^*)$ represents the size of domestic consumption of tradables relative to world consumption of tradables. This variable depends on aggregate demand in the economy, which is determined by the trade balance b . This result should be interpreted as follows: the richer the country is, the larger deficit in the trade balance it can afford, and the more it can spend on consumption.

Finally, the model is closed by the equilibrium for demand and supply of domestically produced nontradables and tradables. Demand for domestic tradables Y_H from home and foreign consumers (using $Y_H = C_H + C_H^*$ and the demand equations (3) and (4) again) can be written as:

$$P_H Y_H = \frac{(1-\alpha^*)}{\alpha^* \tau^{1-\eta^*} + (1-\alpha^*)} P_T^* C_T^* + \frac{\alpha}{\alpha + (1-\alpha)\tau^{1-\eta}} P_T C_T$$

Supply of Home tradables follows from the resource constraint for labour (6) and the production allocation (8). Upon substitution for Y_H one obtains the condition:

$$\frac{q}{1 + \lambda p_n^{\psi(1+\beta)}} = \left[\frac{1-\alpha^*}{\alpha^* \tau^{1-\eta^*} + (1-\alpha^*)} + \frac{\alpha}{\alpha + (1-\alpha)\tau^{1-\eta}} h \right] \tau^{1+\beta} \quad (10)$$

where $p_n = P_N / P_H$, and q collects the exogenous terms, $q = \frac{M_H L}{P_T^* C_T^* / P_F}$ indicating the size of the domestic economy relative to the rest of the world. Similarly, equilibrium between supply and demand for nontradables, $C_N = Y_N$, can be found to require:

$$\frac{q \lambda p_n^{\psi(1+\beta)}}{1 + \lambda p_n^{\psi(1+\beta)}} = \frac{1-\gamma}{\gamma} x^{1-\theta} \left(\frac{\tau}{p_n} \right)^{1+\beta} h \quad (11)$$

where again the left hand features supply and the right hand demand which depends on prices τ , x and aggregate demand represented by h . Finally, noting that the price of nontradables to home tradables p_n relates to the terms of trade τ and the price of nontradables to tradables x as (from (2)):

$$p_n = x \left[\alpha + (1-\alpha)\tau^{1-\eta} \right]^{\frac{1}{1-\eta}} \quad (12)$$

It can be concluded that equations (9) – (12) solve the model in terms of the endogenous price variables x , τ , p_n and the size of tradables consumption h for any given value of the trade balance b .

4. Simulations

In contrast to Obstfeld and Rogoff (2005) who apply their model to the case of the US in the short run, we focus on the case of a small open economy in the medium to long run. In particular we take the case of the Netherlands as a starting point. For many years the Netherlands has run a large surplus in its current account yielding an accumulation of foreign assets. These assets will be used for consumption as ageing progresses. At the same time the share of nontradables consumption increases as a result of ageing. Table 3 gives the evolution of two exogenous variables that determine the change in demand for tradables and nontradables over time. These data follow from Figure 1 and the Tables 1 and 2 in Section 1.

Table 3 Evolution of exogenous variables over time

Exogenous variables		2010	2025	2040
Trade balance at constant prices(% GDP)	b'	7 %	4 %	-3 %
Share of tradables in domestic consumption (baseline)	γ	0.405	0.395	0.387
Share of tradables in domestic consumption (high care scenario)	γ	0.405	0,381	0,356

For expositional reasons Table 3 expresses the trade balance as a percentage to GDP (indicated by b') rather than world consumption as in the model (denoted by b).⁸ From a surplus of 7 per cent of GDP the trade balance is projected to fall to 4 percent in 2025, and a deficit of 3 percent in 2040 when ageing reaches its peak. This reflects the increasing consumption out of wealth when population on average becomes older. The increasing weight of the elderly also changes the composition of consumption. For the share of tradables in consumption (γ) we follow Table 1 for the baseline scenario and Table 2 for the alternative scenario with high growth of healthcare expenditures. As elderly spend more on nontradables (services) the share of tradables decreases from 40.5 percent in 2010 to 38.7 percent in 2040 in the baseline scenario. Admittedly, the share of tradables may be underestimated as a part of public spending might be tradable. On the other hand Obstfeld and Rogoff (2005) emphasize that figures based on micro data like the Dutch household survey tend to overestimate the weight of traded goods as they neglect the fact a substantial component in the value of tradables actually concerns nontradable services. For that reason Obstfeld and Rogoff adopt a low value of $\gamma=0.25$ (or 25 percent). Our estimate of 40.5 percent is higher, which makes sense for a small open economy as the Netherlands. In the alternative scenario with higher growth of long term and healthcare expenditures the share of tradables even declines to 35.6 per cent in 2040.

⁸ We assume that the size of the domestic economy relative to the world economy is constant over time in the underlying original projection. Then we can rescale the trade balance to GDP rather than world tradables consumption as in the model.

It should be noted that the figures for the trade balance are calculated under the assumption of constant domestic prices (Van der Horst et al. 2010). As domestic prices do vary in our analysis we have to take account of the impact of domestic prices on GDP as well. As a result the actual trade balance may worsen less than projected in Table 3 if GDP increases in value thanks to improving terms of trade. In solving the model we assume that the time path trade balance expressed in foreign prices is not affected. This makes sense as the trade balance follows from time path of the stock of net foreign assets given the intertemporal budget constraint, and assuming that the tilt of this time path is not affected itself. This seems the relevant benchmark for this exercise.⁹ To put it differently, if domestic prices rise, domestic consumers can buy fewer domestic goods in return for their accumulated savings. Accordingly, the real rate of return on savings decreases. Technically, this implies that the change in the trade balance is fixed in terms of foreign prices, but endogenous in domestic prices.

Furthermore, it should be taken into account that also the rest of the world faces ageing. This may increase demand for nontradables in the rest of the world as well. What matters, however, is to what extent the position of the Netherlands is distinct from the rest of the world, and it is clear that the Dutch economy features a substantial surplus in the trade balance, which can be expected to turn into a deficit in the long run. The change in demand between tradables and nontradables in the rest of the world is neutralized in our analysis by taking prices of foreign tradables as numeraire, also for the rate of return on international savings.

Parameters of the model

For the parameters of the model we take Obstfeld and Rogoff (2005) as a starting point, but we have to adjust theirs to the case of the Netherlands. The resulting parameters are summarized in Table 4.

⁹ In this analysis we take private saving behaviour as given. Whether the higher intertemporal price of consumption induces higher or lower private savings depends on substitution and income effects.

Table 4 Summary of other parameter variables

Parameter	2	Baseline	Alternatives
Share of H goods in tradables consumption	α	0.5	0.25
Share of F goods in tradables consumption (foreign)	α^*	0.99	
Labour allocation nontradables - tradables	λ	1.239	
Size of the domestic economy (relative to world tradables)	q	0.0387	
Elasticity of substitution H and F tradables	η	2	3; ∞
Elasticity of substitution H and F tradables (foreign)	η^*	2	3; ∞
Elasticity of substitution tradables and nontradables	θ	1	2
Elasticity of substitution labour supply (medium term)	ψ	0	
Elasticity of substitution labour supply (long term)	ψ	1	10
Capital elasticity in production	$\beta/(1+\beta)$	1/3	

On the composition of consumption of tradables into Home and Foreign produced goods (α) there is little reliable information. The share of Dutch tradables production in ROW total tradables production is 0.015. This may be considered as a lower boundary for the interval as home bias will make the share of Home good in consumption larger than this. On the high end it is clear that a small country as the Netherlands will feature a lower share of Home goods in consumption of tradables than the US. In the two country world modelled by Obstfeld and Rogoff (2005) assume $\alpha = 0,7$. Taking this into consideration we will take α equal to 0.5 in the baseline, and equal to 0.25 in an alternative scenario with less home bias. A similar approach is followed for α^* , the share of own goods (Foreign) in the ROW's consumption of tradables. Taking again the share of 0.015 of Dutch tradables in world tradables, and thus 0.985 as share for the rest of the world, and allowing for home bias a value of 0.99 for α^* seems reasonable. We assume that home bias does not change over time.

The parameters q and λ indicate the size of the economy. Taking all initial prices in the base year (2010) equal to one (index), q stands for GDP of the country (relative to total ROW consumption of tradables to which all variables are scaled), and λ for the size of the domestic nontradable sector (N) relative to the tradable sector (H). The size for these values is calibrated given the preferences and the size of the trade balance.

For the elasticities we rely on Obstfeld and Rogoff (2005). For the substitution elasticity of Home and Foreign tradables they use both a value of $\theta = 1$ and $\theta = 2$. According to empirical literature a value near $\theta = 1$ is realistic.¹⁰ O&R use the alternative value of 2 in their baseline not to overstate the price effects due to a change in the balance of trade. We will use these same values, also taking 2 as our baseline value. Regarding η empirical research is thin. Pointing to prior work O&R point to values of $\eta = 2$ and $\eta = 3$ as being conservative but plausible. In addition, we also consider the case with infinite elasticity ($\eta = 1000$), which reduces the model to the two-commodity case with nontradables and tradables only.

¹⁰ Ostry and Reinhart (1992) find estimates in the range of 0,66 and 1,3 for a sample of developing countries. For developed countries, values below 1 are more common (see Stockman and Tesar, 1995 and Mendoza, 1991)

The elasticity of labour supply (ψ) reflects the mobility of labour across domestic sectors. For the medium term (2025) we assume zero elasticity, and for the long term (2040) we choose $\psi = 1$ in the baseline, and a higher elasticity of 2 in an alternative scenario. Although there is a wide literature on – the persistence of intersectoral wage differences – knowledge on the intersectoral elasticity of labour supply is scant. It is generally agreed that mobility across sectors is imperfect due to costs of mobility for those already in the labour market, and limited response of educational choice on wage differential for those who enter the labour market (Lee and Wolpin, 2006). We follow Horvath's (2000) estimate of an elasticity of 1 for the US. This is higher than the usual estimates for the elasticity of labour supply (Evers *et al.* 2008). It could be argued that European countries like the Netherlands feature lower elasticities. On the other hand, the long time horizon of our analysis makes a higher elasticity plausible. Balancing these arguments we think that the value of 1 is reasonable for the year 2040, but we will investigate the sensitivity of the results to this assumption using alternative values of 2 and 10. Finally, the elasticity of production with respect to capital ($\beta/(1+\beta)$) is equal to $1/3$, and therefore $\beta=1/2$.

Two scenarios: baseline and high costs of care scenario

The demand shock induced by demographic change manifests itself through changes in the trade balance (b) and the share of tradables in consumption (γ). In general, the changes in demand will be greater in 2040 than in 2025, so one would expect more marked price effects as well. However, as supply is more elastic in the longer run, this will mitigate the price effects. Table 5 presents the results for the baseline scenario and for the alternative scenario with higher growth of care expenditures. Both scenarios feature a substantial increase in domestic prices. The aggregate consumer price P goes up by 15 percent in the baseline and even 21 percent in the alternative scenario with high growth of care expenditures in 2040, that is a yearly price rise of 0.5 percent and 0.6 percent, respectively. Since we have taken foreign prices as numeraire this price increase represents a real appreciation of the exchange rate for the Netherlands. Also the terms of trade improve as – due to the home bias – demand for domestic tradables increases relative to foreign tradables although at a slightly lower pace, namely 9 and 11 per cent in total in the baseline and the high care scenario.

The price rise of nontradables is reflected in the wages in the nontradables sector which increase by 17 percent relative to those in the tradables sector that is 0.5 percent yearly. This is quite a substantial increase, although not unreasonable in comparison to the 0.23 per cent rise reported by Lee and Wolpin (2006) for the services relative to goods industries in the US in the period 1968-2000. However, in that period employment grew 2.23 percent faster in services than in goods industries. In our exercise, employment grows by only 17 percent in total and 0.5 percent yearly. One should be careful in comparing these figures, however. Here we only look at the partial effect of ageing on wages and employment and we neglect all other trends that affect the share of the services industries in total production.

This real appreciation comes to the benefit of domestic producers. As a result total consumption increases by 22 percent in the baseline, and by even more in the high care scenario, namely 24 percent. These beneficial effects arise from the increase in the prices of domestic products on world markets and from the consequential shift in the domestic production allocation tradables to higher valued nontradables. The effects in GDP exceed the impact on consumption¹¹, which is obvious as not all income can be translated into higher consumption since prices increase too. The positive impact on GDP also explains why the deficit in the trade balance turns out to be smaller ex post than in the projections with constant prices that was used as starting point of the scenario's, namely 2.4 percent viz-a-viz 3 the original percent.

Table 5 Results for the baseline and the high costs of care scenario, 2025 and 2040

Variable	Unit	2010	Baseline		High care growth	
			2025	2040	2025	2040
trade balance (b')	%GDP	7	3.6	-2.4	3.5	-2.2
consumer price (P)	index	1	1.07	1.15	1.10	1.21
consumption (C)	index	1	1.07	1.22	1.08	1.24
price nontradables/tradables (x)	index	1	1.10	1.17	1.14	1.23
terms of trade (τ)	index	1	0.98	0.91	0.98	0.89
output nontradables/tradables (σ_N)	index	1	1.04	1.23	1.06	1.34
wage nontradables/tradables	index	1	1.13	1.17	1.20	1.25
employment nontradables/tradables	index	1	1.00	1.17	1.00	1.25

The higher prices also affect the government budget. In particular, prices of nontradables matter as most government expenditures are on nontradables, e.g. health care, education. The price of nontradables can be found to increase by 22 per cent in 2040 in the baseline and 30 per cent in the high care scenario. This clearly affects the government budget as it increases the costs of most expenditure programs. On a yearly basis this increases the costs by an additional 0.7 to 0.9 percentage points. It is evident that could have a dramatic effect on the sustainability of government expenditures, if taken partially. But that would neglect the fact that also the price increase goes hand in hand with additional growth of income as well. The net effect on public finances cannot easily be determined from the analysis at hand, but the size of the effects on prices, consumption and income (see footnote 9) suggest that it could go either way.

Next, consider the medium term effects represented in the table for the year 2025. In this year the ageing process is still underway. Furthermore, production factors are less flexible over this shorter horizon than in the long term. Here we assume zero mobility of labour (not of capital) in the medium

¹¹ The GDP effects (not included in the table) are 27 % and 35 % respectively, in 2040. In 2025 these effects are relatively smaller (11 % and 14 %) as lack of labour mobility inhibits production being reallocated to the higher valued nontradables sector.

term. This can be seen from the last line in Table 5, stating that the allocation of labour over nontradables and tradables sectors is fixed in 2025, while in the long run (the year 2040) the ratio of employment in nontradables and tradables increases by 17 percent. Accordingly, prices of nontradables react relatively stronger in the short run than in the long run. The terms of trade improve only by 2 percent in 2025 which is modest compared to the 9 percent in 2040, also if taken on a yearly basis. Also welfare – as measured by consumption – increases by much less than in with flexible production as in the long run. The yearly increase in consumption is only 0.45 per cent up to 2025, while over the full period to 2040 it increases with 0.66 per year. For the high care scenario a similar story applies.

Smaller price effects in a flexible economy

The baseline scenario features quite conservative assumptions on the flexibility of the Dutch economy; for both the production side and the consumption side we have adopted elasticities at the lower bound of the interval. Table 6 presents the results for the more optimist case on the flexibility of the economy; we adopt a higher parameter for the mobility of labour across the two sectors ($\psi=10$ instead of $\psi=1$), higher substitution elasticities for foreign versus home tradables ($\eta=\eta^*=0.03$ instead of 0.02) and for tradables versus nontradables as well ($\theta=2$ instead of $\theta=1$).

Table 6 Results for the case with higher elasticities in comparison to the baseline

Variable	Unit	2010	Baseline		Higher elasticities	
			2025	2040	2025	2040
trade balance (b')	%GDP	7	3.6	-2.4	3.8	-2.6
consumer price (P)	index	1	1.07	1.15	1.04	1.07
consumption (C)	index	1	1.07	1.22	1.06	1.17
price nontradables/tradables (x)	index	1	1.10	1.17	1.05	1.06
terms of trade (τ)	index	1	0.98	0.91	0.99	0.93
output nontradables/tradables (σ_N)	index	1	1.04	1.23	1.02	1.27
wage nontradables/tradables	index	1	1.13	1.17	1.07	1.02
employment nontradables/tradables	index	1	1.00	1.17	1.00	1.26

In general, this alternative case gives broadly the same results. Thanks to the higher elasticities price effects are dampened while the relocation in production is larger. The increase in the real exchange rate more or less halves compared to the baseline, while the reallocation of labour almost doubles. Interestingly, the impact on relative wages is now even smaller in the long term than in the medium, even in absolute terms. Obviously this is due to the fact that we have raised the parameter for labour mobility in the long run, while keeping it zero for the medium term. Admittedly, zero mobility this is a strong assumption but it illustrates the fact that adjustment in the allocation of production factors

is costly and time-consuming.¹² In general, price effects dominate in the medium term while quantity adjustments are more important in the long run.

Decomposition

In order to gain insight into the underlying determinants of the price increases we perform two exercises, both reported in table 7. First, redo the baseline simulations, but now focusing on the impact of the trade balance solely. We thus neglect the increasing demand for nontradables related to the ageing process; in our model represented by the decline in the preference parameter γ . The results are reported in the first two columns. Comparison with the original baseline brings out that the reversal in the trade balance is by far more important than the age related change in composition of expenditure. For example, of the total increase in prices by 15 per cent, only 2 percent is due to changing preferences, while 13 per cent is caused by the change in the trade-balance. Even the price of nontradables relative to home tradables is largely determined by the trade of balance effect, and not by the change in the composition of expenditures.

Table 7 Results: Alternatives with constant preferences and infinite η 's

Variable	Unit	constant preferences		two commodity	
		2025	2040	2025	2040
trade balance (b')	%GDP	3.7	-2.4	3.7	-2.7
consumer price (P)	index	1.05	1.13	1.05	1.07
consumption (C)	index	1.06	1.20	1.06	1.14
price nontradables/tradables (x)	index	1.07	1.13	1.08	1.11
terms of trade (τ)	index	0.98	0.91	1.00	1.00
output nontradables/tradables (σ_N)	index	1.03	1.17	1.04	1.23
wage nontradables/tradables	index	1.08	1.12	1.13	1.17
employment nontradables/tradables	index	1.00	1.12	1.00	1.17

The last two columns in Table 7 provide insight into the importance of terms of trade effects. Here we assume that home and foreign produced tradables are perfect substitutes ($\eta, \eta^* = \infty$), thus reducing the model to a two commodity case with nontradables versus tradables only. Naturally, the terms of trade (τ) are constant here, and the overall price rise (P) is much smaller than in the baseline, namely 7 per cent in contrast to 15 per cent by 2040. So terms of trade effects matter a lot for the overall price effect. For the sectoral allocation it has a negligible impact though, output of nontradables increases by 23 per cent relative to home tradables, just as in the baseline. Also the wage effects are similar to the baseline.

¹² While labour mobility is zero in the medium term, capital is assumed to be perfectly mobile, which is a strong assumption too.

Sensitivity analysis

Since elasticities over a time horizon of a full generation are very uncertain, we will look in more detail into the sensitivity of the results for each of the parameters. Table 8 presents the partial effects for the main parameters reported for the year 2040. The alternative for the share of home goods in tradables (α) requires a new calibration ($q = .0284$ and $\lambda = 1.239$, the variants in the elasticities did not. In general the effects are modest, and do not change the results in a qualitative way. Note that the effects are reported in percentage points relative to the baseline. As in all cases we increase elasticities – except in the first case where we lower home bias – price effects tend to be dampened, as a result of which the deficit in the trade balance is increased. Let us look into the impact of each parameter in more detail:

Table 8 Partial effects in 2040 of a selection of parameters

		Baseline	$\alpha=0.5$	$\eta=2$	$\eta^*=2$	$\theta=1$	$\psi=1$
		Alternative	$\alpha=0.25$	$\eta=3$	$\eta^*=3$	$\theta=2$	$\psi=10$
Variable	Unit						
trade balance (b')	Δ % points		-0.27	-0.05	-0.08	-0.12	-0.08
consumer price (P)	Δ % points		-7.5	-1.3	-2.1	-3.7	-3.4
consumption (C)	Δ % points		-4.7	-1.1	-2.0	-2.3	-0.9
price nontradables/tradables (x)	Δ % points		-5.5	-0.7	-1.3	-4.9	-7.8
terms of trade (τ)	Δ % points		4.8	1.3	2.2	1.0	-2.3
output nontradables/tradables (σ_N)	Δ % points		-8.0	0.1	0.2	-8.7	11
wage nontradables/tradables	Δ % points		-5.8	0.1	0.1	-6.3	-13.7
employment nontradables/tradables	Δ % points		-5.8	0.1	0.1	-6.3	15.9

A lower home bias in domestic consumer preferences ($\alpha=1/4$) makes the consumption price less sensitive to changes in domestic aggregate demand because a larger share of consumption is spent on foreign tradables. In comparison with the baseline consumer prices rise by 7.5 percentage point less, or 7.5 per cent instead of 15 per cent. Also the terms of trade effect is smaller which is natural as domestic demand is less important domestic tradables producers. Also, fewer resources are relocated to the nontradables sector as prices of nontradables increase less. This is because with smaller home bias a smaller change in total consumer spending is necessary to achieve a given reversal in the trade balance.

Higher substitution elasticities with regard to home and foreign tradables of domestic and foreign consumers (η, η^*) lead to smaller price effects as expected. Foreign preferences seem to matter more than preferences of domestic consumers. As it is easier to substitute between home and foreign tradables, there will be stronger reallocation effects between domestic tradables and nontradables sectors as nontradables become relatively scarcer.

Better substitutability between tradables and nontradables in particular reduces the impact on the relative tradables-nontradables price (x). Accordingly, scarcity in the nontradables sector will increase less resulting in smaller wage and price increases and lesser reallocation of resources. The increase in output of nontradables relative to tradables (σ_N) diminishes by 8.7 percentage points from 23 per cent to about 14 per cent. Finally, larger mobility of labour resulting from a higher ψ leads to a larger reallocation in production – at a smaller wage differential – which dampens the prices effects for consumers. The terms of trade effect increase though, as domestic tradables become scarcer on international markets.

5. Conclusion

There are concerns that there will be too little resources in the future to take care of the old when ageing reaches its peak in 2040. Does this analysis take away these concerns? Yes and no. That ageing of the Dutch population will lead to increasing demand for nontradables (services) in the long run is for sure. Whether this will lead to scarcity and rising wages and prices in the nontradables sector is less certain. This depends on the flexibility of the economy to reallocate resources from the tradables to the nontradables sector on the one hand, and the flexibility of consumers to switch to other, tradable goods and services on the other hand.

Adopting – in our view – conservative estimates on the flexibility of workers and consumers, we find that consumption prices may rise by 15 to 21 per cent in total depending on whether you take the baseline projection on ageing or the alternative projection with high growth of care. This amounts to a yearly rise in the real exchange rate by 0.5 to 0.6 per cent. Prices of nontradables increase by even more, 0.7 to 0.9 per cent, thereby putting further pressure on the public finances. Interestingly, the change in composition of consumer expenditures plays only a minor role here; it is the unwinding of the trade balance surplus that dominates these results.

Our findings are however sensitive to how flexible we regard the economy over a time horizon of a full generation. Unfortunately, the empirics of such a long time horizon is very thin. Looking at wage differentials we do not see big swings in reaction to changes in the large shifts in sectoral allocation that happens in the past, for example the demise of employment in agriculture and the rise of services industries. Therefore, we interpret the elasticities adopted by Obstfeld and Rogoff in the analysis of the US balance of trade reversal as being at the conservative end of the spectrum. At the same time, neglecting real exchange rate effects at all may be naïve as well. Therefore it is important to explore the potential prices effects as we have done in this study.

There are some interesting lessons to be drawn. First of all, while future scarcity of nontradables may drive up the cost of private and public consumption, it will also lead to gains in income through improvement in the terms of trade. On balance, larger scarcity might lead to higher consumption and higher welfare in the long run. Whether this helps the ageing problem depends on which generations benefit from the gains in income. It seems plausible that this will be the younger

working generations. This suggests that these income effects help to diminish the ageing problem, indeed.

One should however be careful in drawing conclusions on welfare, as our analysis is partial and does not represent a full dynamic general equilibrium approach. For example, an interesting issue to be explored in future research is how the real appreciation affects optimal saving behaviour and policies with regard to the ageing problem. Rising domestic prices will lower the real interest rate which might make strategies to increase national savings as a remedy for the ageing problem less attractive. This not only pertains to fiscal policies of the government, but also to the ambition level of pensions. If real interest rates decline, should not we enjoy current consumption more than future consumption?

Appendix . Tradables and nontradables

This appendix discusses the classification of goods into tradables and nontradables in more detail.

Private consumption

The Dutch Household Survey (CBS Budget Onderzoek) aims to chart consumer spending per household according to size, composition and means of financing. This survey permits to track expenses on more than 400 types of goods and services. We classify each of these 400 types into tradable or nontradables applying the simple rule that goods are tradable and services are nontradable. This approach is pragmatic and driven by limitations of the data. A better solution would be to determine for each category how much imported or exported and set a level of 'tradability'. Yet, data on international trade are lacking at this level of aggregation. Table A1a presents the eight aggregated categories. Table A1b allocates all 400 types of consumption to these categories according to whether they are classified as tradable or nontradable.

Table A1a. Recoding of original categories into 8 categories

Goods and services categories	Classification number
Food and drinks	11
Housing	22
Fuel, gas and electricity	33
Health and personal hygiene	44
Education	550
Leisure	551 + 553 + 556
Transportation	557

Table A1b. Recoding of original categories into dichotomy tradables vs. nontradables

Tradables	
Food and drinks	110 + 111 + 113 + 115 + 116 + 118 + 1190 + 1198
Housing	224 + 2260 + 2265 + 2267 + 2268 + 2270 + 2275
Fuel, gas and electricity	330 + 3350 + 3360 + 3370 + 3375 + 3382
Health and personal hygiene	4410 + 442000 + 442100 + 442200 + 443100 + 444100 + 44600 + 44610 + 44700
Education	550200 + 5504
Leisure	551200 + 55160 + 55210 + 55250 + 5535 + 554300 + 554350 + 554400 + 5551 + 556 + 557200 + 557400
Transportation	5576 + 558100 + 5582

Table A1b. (continued)

Nontradables	
Food and drinks	1193
Housing	220 + 2278 + 2280
Fuel, gas and electricity	3376 + 3380
Health and personal hygiene	4400 + 442300 + 443000 + 444000 + 44620 + 44720 + 4490 + 4590
Education	550000 + 550100 + 550150
Leisure	550300 + 551100 + 551400 + 55170 + 55180 + 55190 + 5530 + 554600 + 554650 + 554700 + 554750 + 554800 + 554900 + 555000
Transportation	5570 + 557300 + 557500 + 557700 + 557900 + 558000 + 558060 + 558070
Other	66

The next step is to establish the consumption profiles by age groups. These follow simply from adding up the expenditures per category for the two age groups. Subsequently the budget shares can be established. Table A2 presents the budget shares for people of working age (20-64) and the elderly age (65 or older).

Table A2. Shares private consumer spending per age group

Categories	Age groups	
	20-64	65+
Food and drinks	15 %	16 %
Housing	39 %	51 %
Clothing	11 %	10 %
Medical care and hygiene	10 %	9 %
Education	4 %	5 %
Leisure	9 %	4 %
Transportation	13 %	8 %
Other	13 %	9 %
Tradables	52 %	45 %
Nontradables	48 %	55 %

Source: own calculation, based on CBS (2010)

Public spending per household

The Household Survey only covers private consumption. For our analysis we need the evolution of public spending as well. The long term budgetary projections by Van der Horst et al., (2010) provide information on the age profile of government expenditures. Government transfers to households are not taken into account as these are already indirectly included in the Household Survey as they are part of the private income of the beneficiaries. Table A3a presents public spending and total private per age group. Not all government expenditures can be allocated to individual households (e.g. military expenses, police); these are evenly distributed over all individuals.

Table A3a. Government expenditures per person pe age group, 2007 (in Euro's per person)

	Age groups	
	20-64	65+
Public spending		
Education	346	0
Health care	1.019	4.406
Non age specific	3.062	3.062
Total public consumption	4.427	7.468
Total private consumption	20.710	14.553

Source: own calculation, based on Van der Horst *et al.* (2010), Eurostat (2011) and CBS (2010)

As the data on private consumption is on household level and our calculations focus on individuals, the amounts of private spending (the last line of Table A3a) are corrected via an equivalence factor provided by Eurostat (2011). Table A3b gives an update of Table A2 with public being included. As all public expenditures are assumed to be nontradable, the share of nontradables increases substantially.

Table A3b. Shares private consumer spending per age group

Categories	Age groups	
	20-64	65+
Food and drinks	13 %	11 %
Housing	30 %	31 %
Clothing	6 %	4 %
Medical care and hygiene	9 %	27 %
Education	5 %	2 %
Leisure	12 %	6 %
Transportation	16 %	10 %
Other	10 %	10 %
Tradables	47 %	32 %
Nontradables	53 %	69 %
<i>private expenditure</i>	<i>42 %</i>	<i>40 %</i>
<i>public expenditure</i>	<i>11 %</i>	<i>29 %</i>

Source: own calculation, based on Van der Horst *et al.* (2010) Eurostat (2011) and CBS (2010)

Ageing and budget shares

Finally, Table A4 presents the most recent forecasts on the shares of people of working age and retirees (CBS, 2010). As the dependency ratio doubles between 2010 and 2040, the weight of the consumption profile of the elderly will increase considerably. Combining the demographic forecasts and the consumption profiles it is possible to determine future aggregated budget shares. Table A4 gives the results for the baseline scenario. Van der Horst *et al.* (2010) also provide an alternative

scenario with high growth of care expenditures; the results for this alternative scenario are given in section 2 as well.

Table A4. Development demographics and share of nontradables

Demographic projections	2010	2025	2040
Share working age population*	80,3 %	72,9 %	67,2 %
Share elderly*	19,7 %	27,1 %	32,8 %
Dependency ratio	0,25	0,37	0,49
Projections for the budget shares - baseline scenario	2010	2025	2040
Share tradables, private consumption	40,5 %	39,5 %	38,7 %
Share nontradables, private consumption	38,7 %	38,5 %	38,3 %
Share public spending	20,8 %	22,0 %	23,0 %
<i>Share nontradables and public spending</i>	<i>59,5 %</i>	<i>60,5 %</i>	<i>61,3 %</i>
Projections for the budget shares - high growth of care scenario	2010	2025	2040
Share tradables, private consumption	40,5 %	38,1 %	35,6 %
Share nontradables, private consumption	38,7 %	37,1 %	34,8 %
Share public spending	20,8 %	24,8 %	29,6 %
<i>Share nontradables and public spending</i>	<i>59,5 %</i>	<i>61,9 %</i>	<i>64,4 %</i>
* Share as part of population aged 20 years and older			
** Current value, based on own calculations, see Table A3
